Abstract. The main objective of this lecture is to make the end users aware of the various physical phenomena and especially of the errors frequently met during temperature and heat flow measurement. Phenomena which occur in thermometry with contact (thermoelectric effect, thermoresistance…) and without contact (pyrometry with single, two colors or multiwavelength) will be presented. For thermometry with contact, the analysis of systematic errors related to the local disturbance of field temperature due to the introduction of sensors will be emphasized. Indeed intrusive effects due to sensors are usually ignored and can be reduced using know how as will be shown through analytical modeling. Otherwise, interests of using semi intrinsic thermocouples will be discussed. The specificities of temperature measurement in fluid flow and for semi transparent material will be detailed. Finally heat flow measurement using direct methods (gradient, enthalpic, electric dissipation …) or inverse methods (heat flow sensors with network of thermocouples) will be reminded. This lecture is also dedicated to non contact thermometry. Specificities of radiative methods and procedures to overcome bias in temperature measurement will be discussed. The amount of thermal radiation emitted by a surface is only a fraction of the blackbody radiation at the same temperature. This ratio, i.e. the emissivity, is an additional unknown parameter. Whatever the number of considered wavelengths in passive radiation thermometry, one faces an underdetermined problem, notwithstanding the fact that the atmosphere between the sensed surface and the sensor introduces itself additional unknown parameters. We will present several solutions (and some pitfalls) for the problem of emissivity and temperature separation developed in the field of multiwavelength pyrometry (MWP) and in the field of multiwavelength/hyperspectral remote sensing of earth.
1. Introduction: General notions about temperature sensors

Mediums are in interaction with the environment, the interaction can be of several types: thermal, electrical, magnetic, liquid or vapor mass transfer, chemical reaction, corrosion ... The installation of sensor on or inside the mediums should not modify these interactions. The choice of the sensor is performed so that these interactions do not have an effect on the measurement and on the lifespan of the sensor. For example, a sensor on a surface can modify heat transfer by conduction, convection or radiation. Otherwise, the deposit of a liquid film or a coating modifies emissivity and therefore the radiative heat exchanges. The main consequences is that the temperature provided by the sensor can be very different from the one to measure. One important thing to keep in mind is that temperature measurement is accompanied by parasitic effects which must be well-known.

According to the type of interaction between sensor and medium, one can classify the methods of measurement in three categories:

1. **Methods with direct contact sensor-medium**: in this type of method, the sensor tends to locally equilibrate itself with the medium. If there is perfect adiabaticity of the sensor with the environment, its temperature is equal to that of the medium. However, in thermometric devices, this adiabaticity is usually not perfect.

2. **Methods with contact without physical connection with the environment**: in some cases, the temperature readings is carried out using an optical mean therefore no physical connection exists between the sensor and the environment. In this category, we can found surface temperature measurement with deposited thermosensitive material such as liquid crystals or photoluminescent salts.

3. **Methods without contact**: in this method sensors are far from the medium. Despite there is still interactions between them, the sensor is no more in equilibrium with the medium. Such methods are essentially based on radiative heat transfer.

In this lecture, one will discuss temperature measurement using these methods. A focusing on the main methods (thermoelectric, radiative) will be done. First of all temperature measurement using thermoelectric effects will be analyzed in various situations (temperature measurement in fluids, in semi transparent medium and in opaque medium). Then recent progress for temperature measurement using radiative methods will be presented.

2. Thermometry with contact: thermoresistances, thermocouples

2.1. Phenomena and sensors for temperature measurement

2.1.1. Thermoresistances

2.1.1.1. Metallic probes

They are commonly called Resistance Temperature Detectors (RTD). The thermosensitive parameter in these sensors is the electrical resistance. This one changes according to empirical law such as:

\[ R = R_0 [1 + a (T - T_0) + B (T - T_0)^2] \]

Their respective sensitivities, \( a \), are about \( 10^{-3} \) K\(^{-1} \) that is rather weak, but their accuracy is rather large and higher than that of the thermocouples (table 2.1.). In the specified temperature range, their stability is good. The resistor probes have an almost linear answer. A resistance measurement device or a power supply with a low voltage voltmeter has to be used inducing a current about a few mA through the thermoresistive probes. One has to take care about self heating or Joule effect in order to limit temperature bias. For practical applications, the thermoresistive probes are composed of a metallic layer deposited on a flat electrical insulating substrate (epoxy resin, ceramic, mica...).
cylindrical (glass, pyrex….). The size and the shape of these thermoresistive probes make them useful for average temperature measurement. In addition, their time constant is much larger than that of thermocouples due to their insulating substrate. Therefore they will be used preferentially for temperature measurement in stationary mode.

\begin{table}[h]

\begin{tabular}{l|c|c}
\hline
Metal & Sensitivity (K$^{-1}$) & Temperature range (°C) \\
\hline
Platinum & 4 10$^{-3}$ & -200 à +1000 \\
nickel & 6 10$^{-3}$ & -190 à +350* \\
Copper & 4 10$^{-3}$ & -190 à +150** \\
\hline
\end{tabular}
\caption{Characteristics of the main thermoresistive metallic probes}
\end{table}

*: 358°C=Curie point for Nickel (magnetic transformation)
**: risk of oxydation for copper

2.1.1.2. Thermistors

The thermistors which are probes with semiconducting material are much more sensitive than the metallic probes (sensitivity 10 times larger), but they are less stable and their calibration curve is strongly nonlinear: \( R = R_0 \exp \left[ B \left( \frac{1}{T} - \frac{1}{T_0} \right) \right] \).

The thermistors are presented in several shapes: pearl, disc or rod. The pearls are made of semiconducting material dropped on two connecting wires. Their diameter is about 0.15 to 2.5mm. They can be coated with glass. The flat discs are of more important size (2 to 25 mm in diameter and 0.5 to 12 mm thick). The rods are metalized at their extremity for the contact with the connecting wires. Their time constant ranges from a few seconds to several tens of seconds and the temperature range for thermistors goes usually from -50°C to 500°C.

2.1.2. Thermoelectric effects: theory and practice

The thermocouple is the most widely electrical sensor in thermometry and it appears to be the simplest of electrical transducers. Thermocouples are inexpensive, small in size, rugged, and remarkably accurate when used with an understanding of their peculiarities. Accurate temperature measurements are typically important in many scientific fields for the control, the performance and the operation of many engineering processes. A simple thermocouple is a device which converts thermal energy to electric energy. Its operation is based upon the findings of Seebeck [1]. When two different metals \( A \) and \( B \) form a closed electric circuit and their junctions are kept at different temperatures \( T_1 \) and \( T_2 \) (Figure 2.1), a small electric current appears.

\begin{figure}[h]
\centering
\begin{tikzpicture}
\draw (0,0) circle (1cm);
\node at (0,0) {Metal A};
\node at (-1,1) {T_2};
\node at (1,1) {T_1};
\draw[thick,->] (0,0) -- (1,0);
\draw[thick,->] (0,0) -- (-1,0);
\draw[thick,->] (0,0) -- (0,1);
\node at (0,-1) {Metal B};
\end{tikzpicture}
\caption{Thermocouple circuit.}
\end{figure}

The electromotive force, emf, produced under these conditions is called the Seebeck emf. The amount of electric energy produced is used to measure temperature. The electromotive force depends on materials used in the couple and the temperature difference \( T_1-T_2 \). Seebeck effect is actually the combined result of two other phenomena, Peltier effect [2] and Thomson effect [3]. Peltier discovered
that temperature gradients along conductors in a circuit generate an emf. Thomson observed the existence of an emf due to the contact of two dissimilar metals and related to the junction temperature. Thomson effect is normally much smaller in magnitude than the Peltier effect and can be minimized and disregarded with proper thermocouple design.

**a) Peltier effect**

A Peltier electromotive force \( V_M - V_N \) is created at the junction of two different materials (wire or film) A and B, at the same temperature \( T \), depending on the material and the temperature \( T \) (Figure 2.2):

\[
V_M - V_N = \Pi_{AB}^{T}
\]

(2.1)

\( \Pi_{AB} \) is the Peltier coefficient at temperature \( T \).

\[\begin{array}{c|c|c|c|c}
T & A & M & N & B \\
\hline
\Pi_{AB}^{T} & & & & \\
\end{array}\]

Figure 2.2. Peltier effect without current flow.

\[\begin{array}{c|c|c|c|c}
T & A & I & B & \\
\hline
Q_p & & & & \\
Heat flow & & & & \\
\end{array}\]

Figure 2.3. Peltier effect with current flow.

When a current \( I \) flows through a thermocouple junction (Figure 2.3), heat, \( Q_p \), is either absorbed or dissipated depending on the direction of current. This effect is independent of Joule heating.

\[
dQ_p = (V_M - V_N)Idt = \Pi_{AB}^{T}Idt
\]

(2.2)

\( Q_p \) is the heat quantity exchanged with the external environment to maintain the junction at the constant temperature \( T \).

The phenomena is reversible, depending on the direction of the current flow and:

\[
\Pi_{AB}^{T} = -\Pi_{BA}^{T}
\]

(2.3)

**b) Volta’s law**

In an isothermal circuit composed by different materials, the sum of the Peltier EMFs are null (Figure 2.4) and:

\[
\Pi_{AB} + \Pi_{BC} + \Pi_{CD} + \Pi_{DA} = 0
\]

(2.4)

\[\begin{array}{c}
\Pi_{BC} \\
\Pi_{CD} \\
\Pi_{DA} \\
\end{array}\]

Figure 2.4. Volta’s law with four materials.
c) Thomson effect

Thomson EMF’s corresponds to the tension \( e_A(T_1, T_2) \) between two points M and N of the same conductor, submitted to a temperature gradient, depending only on the nature of the conductor (Figure 2.5):

\[
e_A(T_1, T_2) = \int_{T_1}^{T_2} \tau_A dT
\]

(2.5)

Where \( \tau_A \) is the Thomson coefficient of the material A.

![Figure 2.5. Thomson effect without current flow.](image1)

![Figure 2.6. Thomson effect with current flow.](image2)

When a current \( I \) flows through a conductor within a thermal gradient \( (T_1 - T_2) \), heat \( Q_T \), is either absorbed or dissipated (Figure 2.6):

\[
dQ_T = e_A(T_1, T_2) I dt = \int_{T_1}^{T_2} \tau_A dT I dt
\]

(2.6)

d) Seebeck effect

When a circuit is formed by a junction of two different metals A and B and the junctions are held at two different temperatures, \( T_1 \) and \( T_2 \), a current \( I \) flows in the circuit caused by the difference in temperature between the two junctions (Figure 2.7).

![Figure 2.7. Seebeck effect.](image3)

![Figure 2.8. Seebeck Voltage.](image4)

The sum of the different Peltier and Thomson EMF for the circuit corresponds to the Seebeck EMF:

\[
E_{AB}(T_2, T_1) = \Pi_{AB} + \int_{T_1}^{T_2} \tau_B dT + \int_{T_2}^{T_1} \tau_A dT
\]

(2.7)
Then, the Seebeck EMF becomes:

\[ E_{AB}(T_1, T_2) = \sigma_{AB}(T_1 - T_2) \]  \hspace{1cm} (2.8)

\( \sigma_{AB} \) is the Seebeck coefficient for the A and B metals of the couple (\( \mu V/°C \) or \( \mu V/K \)). This coefficient corresponds to a constant of proportionality between the Seebeck voltage and the temperature difference.

If the circuit is open at the center of the circuit (Figure 2.8), the net open voltage is a function of the junction temperature and the composition of the two metals.

The thermoelectric power, or sensitivity, of a thermocouple is given by Table 2.2:

\[ \sigma_{AB} = \frac{dE_{AB}}{dT} \]  \hspace{1cm} (2.9)

2.2. Temperature measurement in fluids

2.2.1. Mathematical modelling

Transient phenomena appear in many industrial processes and many researchers and engineers have been paying attention to the measurement of temperature fluctuations in turbulent reacting flows, compressible flows, boiling, cryogenic apparatus, fire environments, under the condition of...
simultaneous periodical variations of velocity, flow density, viscosity and thermal conduction in gas [7-14].

There has been considerable progress in recent years in transient thermometry techniques. Some of these techniques are applicable for both solid material characterization while others are suitable only for fluids thermometry. This chapter deals only with temperature thermocouples measurements in fluids (gases and liquids). Many concepts involved in the temperature measurements in fluids are common to both types and they are discussed here. The techniques for temperature measurement in a fluid consists in inserting a thermocouple, allowing it to come to thermal equilibrium and measuring the generated electrical signal. When a thermocouple is submitted to a rapid temperature change, it will take some time to respond. If the sensor response time is slow in comparison with the rate of change of the measured temperature, then the thermocouple will not be able to faithfully represent the dynamic response of the temperature fluctuations. Then, the problem is to measure the true temperature of the fluid because a thermocouple gives its own temperature only. The temperature differences between the fluid and the sensor are also influenced by thermal transport processes taking place between the fluid to be measured, the temperature sensor, the environment and the location of the thermocouple. Consequently, the measured temperature values must be corrected. Whereas in steady conditions only the contributions of the conductive, convective and radiative heat exchanges with the external medium occur, unsteady behavior introduces another parameter which becomes predominant: the junction thermal lag which is strongly related to its heat capacity and thermal conductivity. The corrections generally decrease with the thermocouple diameters, and both temporal and spatial resolutions are improved. However, while spatial resolution is fairly directly connected with the thermocouple dimensions, the temporal resolution doesn’t only depend on the dimensions and the thermocouple physical characteristics, but also on the rather complex heat balance of the whole thermocouple. To obtain the dynamic characteristics of any temperature probe, we analyze its response to an excitation step from which the corresponding first time constant $\tau$ can be defined as:

$$\tau = \frac{\rho c V}{h A}$$

(2.10)

$\tau$ is the time constant, $\rho$ the density, $c$ the specific heat, $V$ the volume of the thermocouple and $A$ the area of the fluid film surrounding the thermocouple while $h$ is the heat transfer coefficient.

The goal of this work consists in calculating or measuring time constants of thermocouples and comparing their behavior according to different dynamical external heating like convective, radiative and pseudo-conductive excitations.

An accurate calibration method is an essential element of any quantitative thermometry technique and the goal of any measurement is to correctly evaluate the difference between the “true” temperature and the sensor temperature. Figure 2.9. shows the energy balance performed at the butt-welded junction of a thermocouple for a junction element $dx$ resulting from the thermal balance between the rate of heat stored by the junction $d\hat{Q}_{st}$ and heat transfer caused by:

- convection in the boundary layer around the thermocouple $d\hat{Q}_{cv}$
- conduction along the wires $d\hat{Q}_{cd}$
- radiation between the wires and the external medium $d\hat{Q}_{rad}$
- contribution of another source of heat power (a laser source in this example) $d\hat{Q}_{ext}$. 

Lecture 5: Measurements with and without contact in heat transfer: page 8
During a transient period, because of its thermal capacity, the thermocouple temperature will lag behind any gas temperature variation. This leads to an error from which a thermocouple time constant can be defined. The general heat balance for a junction of length $dx$ is expressed as:

$$d\dot{Q}_{th} = d\dot{Q}_{cv} + d\dot{Q}_{cd} + d\dot{Q}_{rad} + d\dot{Q}_{ext} \quad (2.11)$$

The thermoelectric junction stores the heat by unit time $d\dot{Q}_{th}$:

$$d\dot{Q}_{th} = \rho_{th}c_{th}\frac{\pi d^2}{4} \frac{\partial T_{th}}{\partial t} dx \quad (2.12)$$

where $\rho_{th}$, $c_{th}$ and $T_{th}$ are the density, the specific heat and the temperature of the junction respectively. The junction is approximated by a cylinder whose diameter equals the wire diameter $d$. This does not exactly fit reality but remains currently used in numerical calculations [15-21]. Moreover, if the wires are uniformly curved, the observation near the junction confirms the previous assumption (Figures 3.20 and 3.21). The Newton’s law of cooling is:

$$d\dot{Q}_{cv} = \pi dx \text{Nu} \lambda_g \left( T_g - T_{th} \right) \quad (2.13)$$

where $\lambda_g$ and $T_g$ are the thermal conductivity and the static temperature of the gas. The difficulty is to obtain an accurate relation between the Nusselt number $\text{Nu}$ and the flow characteristics around the junction assumed as a cylinder [17, 22-25].

Indeed, such a thermocouple is surrounded by both a thermal and aerodynamic gradient which acts as a thermal resistance that is estimated from empiric approaches. A purely convective heat transfer coefficient $h$ is generally deduced from correlations about the Nusselt number that is generally expressed as a combination of other dimensionless numbers, such as Eckert, Reynolds, Prandtl or Grashof numbers. However, if many cases have been investigated, the example of thin cylinders cooling process is still an open question. Table 2.4 gives a list of the main Nusselt correlations in this particular case.
Table 2.4 Heat transfer laws – These laws describe the heat transfer from a cylinder of infinite length. The film temperature $T_{film}$ is defined as the mean value between the fluid temperature $T_f$ and the thermocouple temperature $T_{th}$ \[16-18, 20-25, 29-33\]

</tbody>
</table>
Conduction heat transfer \( d\dot{Q}_{cd} \) that occurs along the wires to the thermocouple supports has the following general expression:

\[
d\dot{Q}_{cd} = \lambda_{th} \frac{\pi d^2}{4} \frac{\partial^2 T_{th}}{\partial x^2} dx
\]  

(2.14)

However, different studies and experiments have shown that conduction dissipation effects along cylindrical wires can be neglected when the aspect ratio between the length and the diameter is large enough \([6, 26-32]\). Indeed, practical cases of anemometry and thermometry have led to fix a condition such:

\[ L/d > 100 \]  

(2.15)

Hence, the temperature gradient can be considered null in the axial direction of the thermocouple wire. The thermocouple is placed in an enclosure at temperature \( T_w \). The enclosure dimensions are assumed to be large with respect to the probe dimensions. Then, the influence of the radiative heat transfer can be expressed by the simplified form:

\[
d\dot{Q}_{rad} = -\sigma \varepsilon(T_{th}) \left( T_{th}^4 - T_w^4 \right) dS_{ray}
\]  

(2.16)

\( \sigma \) is the Stefan Boltzmann constant and \( \varepsilon(T_{th}) \) the emissivity of the wire at the temperature \( T_{th} \). The exchange surface of the radiative heat transfer \( dS_{ray} = \pi d dx \) nearly equals the surface exposed to the convective heat flux. This supposes that the radiative heat transfer between the sensor and the walls is greater than between the gas and the sensor. Here, the assumption is that the gas is transparent, however it is not satisfied in several practical applications like temperature measurements in flames.

In section 2.2.1.b we will consider a radiative calibration so that the thermocouple junction is submitted to an external heat contribution \( d\dot{Q}_{ext} \) produced by a laser beam \([27]\).

\[
d\dot{Q}_{ext} = \sqrt{\frac{2}{\pi}} \frac{(1-R)}{a} P_L \text{erf} \left[ \frac{d}{a\sqrt{2}} \right] \exp \left[ -2 \frac{x^2}{a^2} \right] dx
\]  

(2.17)

\( P_L \) is the laser beam power, \( R \) the mean reflection coefficient of the thermocouple junction surface, \( d \) the diameter of the junction and \( a \) the laser beam radius (this value corresponds to the diameter for which one has 99 % of the power of the laser beam).

The total heat balance of the thermocouple may be written as follows

\[
\rho_{th} c_{th} \frac{\pi d^2}{4} \frac{\partial T_{th}}{\partial t} = \text{Nu} \lambda_{th} \pi \left( T_g - T_{th} \right) + \lambda_{th} \frac{\pi d^2}{4} \frac{\partial^2 T_{th}}{\partial x^2} \\
-\sigma \varepsilon(T_{th}) \left( T_{th}^4 - T_w^4 \right) \pi d + \frac{2}{\pi} \left( 1 - R \right) P_L \text{erf} \left[ \frac{d}{a\sqrt{2}} \right] \exp \left[ -2 \frac{x^2}{a^2} \right]
\]

(2.18)

The expression of the gas temperature \( T_g \) is deduced from equation (2.18):

\[
T_g = T_{th} + \tau_c \left[ \frac{\partial T_{th}}{\partial t} - \frac{\lambda_{th}}{\rho_{th} c_{th}} \frac{\partial^2 T_{th}}{\partial x^2} + \frac{4 \sigma \varepsilon(T_{th})}{\rho_{th} c_{th} d^2} \left( T_{th}^4 - T_w^4 \right) \right]
\]  

(2.19)
Equation 2.19 represents a general expression of the thermocouple dynamic behavior including each of the heat transfer modes. In this expression, the time constant \( \tau_{cv} \) of the thermocouple junction is defined by:

\[
\tau_{cv} = \frac{\rho_l c_l d^2}{4 \, Nu \, \lambda_g} = \frac{\rho_l c_l d}{4 \, h}
\]  

(2.20)

If the radiation, the conduction and the external heat supply are neglected, the gas temperature simplifies to:

\[
T_g = T_{th} + \tau_{cv} \frac{\partial T_{th}}{\partial t}
\]

(2.21)

The time-response of a temperature sensor is then characterized by a simple first order equation. For a step change in temperature, equation (2.21) reduces to:

\[
\frac{T_g - T_{th}}{T_g - T_i} = \exp \left[ -\frac{t}{\tau_{cv}} \right]
\]

(2.22)

where \( T_i \) is the initial temperature.

Conventionally, the time constant \( \tau_{cv} \) is defined as the duration required for the sensor to exhibit a 63\%, \((=1-e^{-1})\) change from an external temperature step, in the case of a single-order equation. Actually, the fact that different kinds of heat transfers are involved should lead to a global time-constant in which the different phenomena contributions are included [16, 29]. As a consequence, the ability of a thermocouple to follow any modification of its thermal equilibrium is resulting from a multi-ordered time response where the most accessible experimental parameter remains the global time constant. The multi-ordered temperature response of a thermocouple can be represented by the general relation:

\[
\frac{T_g - T_{th}}{T_g - T_i} = K_1 \exp \left[ -\frac{t}{\tau_1} \right] - K_2 \exp \left[ -\frac{t}{\tau_2} \right] - \cdots - K_n \exp \left[ -\frac{t}{\tau_n} \right]
\]

(2.23)

\( T_i \) is the initial temperature, \( T_g \) is the fluid temperature. The value of the constants \( K_1, K_2, \ldots, K_n \) as well as the time constants \( \tau_1, \tau_2, \ldots, \tau_n \), depend on the heat flow pattern between the thermocouple and the surrounding fluid.

If experiments have shown that most configurations involve nearly first-order behaviors, the measured time-constant does not allow to isolate each of the different contribution modes.

Therefore, the remaining problem of experiments is to relate this global time-constant to the different implied heat transfer modes. Then, our contribution in this section will be to show the influence of the heat transfer condition on the measured time constant value through three different methods of dynamic calibration.

Classical testing of thermocouples often involves plunging them into a water or oil bath and for providing some information only about the response of the thermocouple under those particular conditions. It does not provide information about the sensor response under process operating conditions where the sensor is used. In order to improve thermocouple transient measurements, a better understanding of the dynamic characteristics of the sensor capability is necessary.

2.2.2. Dynamic calibration

The calibration methods consist of a series of heating and cooling histories performed by submitting the thermocouple to different excitation modes. Then, the resulting exponential rise and decay times of
the thermocouple signals allow to estimate the time constant $\tau$. The thermocouple signal is amplified with a low-noise amplifier having a –3 dB bandwidth of 25 kHz (Gain = 1000). The output voltage is finally recorded by a digital oscilloscope.

\textit{a) Convective calibration}

Figure 2.10. illustrates the convective experimental device. The thermocouple junction is exposed continuously to a constant cold air-stream at constant temperature $T_{MIN}$. A second hot air flow excites periodically the thermocouple and creates a temperature fluctuation of frequency $f$ [33].

**Figure 2.10. Convective characterization setup**

**Figure 2.11. Convective characterization results**

The response of a thermocouple submitted to successive steps of heating or cooling is close to a classical exponential first order response from which the time constant can be determined (Figure 2.11.). It can be deduced from the measurement of four temperatures: $T_{MAX}$, $T_{MIN}$, $T_{th max}$ and $T_{th min}$.

For the heating period $t_h$, we define the temperature differences $\delta_{1h}$ and $\delta_{2h}$:

$$\delta_{1h} = T_{MAX} - T_{th min} \quad \text{and} \quad \delta_{2h} = T_{MAX} - T_{th max}$$

(2.24), (2.25)

For the cooling period $t_c$, the temperature differences $\delta_{1c}$ and $\delta_{2c}$ by:

$$\delta_{1c} = T_{th max} - T_{MIN} \quad \text{and} \quad \delta_{2c} = T_{th min} - T_{MIN}$$

(2.26), (2.27)

Then, the two convective time constants are defined while the thermocouple is heating ($\tau_h$) and cooling ($\tau_c$). If we consider a first order response of the sensor we obtain the expressions:

$$\tau_h = \frac{t_h}{ln(\delta_{1h}/\delta_{2h})} \quad \text{and} \quad \tau_c = \frac{t_c}{ln(\delta_{1c}/\delta_{2c})}$$

(2.28), (2.29)

Then the period of the thermocouple response is:

$$\theta_{resp} = t_c + t_h$$

(2.30)
Figure 2.11 presents temperature histories for a 12.7 \( \mu \text{m} \) K type thermocouple. The excitation frequency is 37 Hz. The velocities of hot and cold air are both 13 m/s\(^{-1}\) at the outlet of the air flow tubes. In any case, the measured time constants are longer during the heating phase than during the cooling one. This phenomenon corresponds to a greater magnitude of the convection coefficient (\( h \)). Table 2.5 presents convective time constants for the different thermocouple diameters, resulting from heating periods only and for two air flow velocities (13 m/s\(^{-1}\) and 23 m/s\(^{-1}\)) and for a 5 to 72 Hz explored frequency bandwidth.

**Table 2.5** Convective time constant \( \tau_{cv} \) (ms) and bandwidth \( \Delta f \) (Hz) versus junction diameters. The thermocouple mechanical resistance is not sufficient for the flows with 13 m/s\(^{-1}\) and 23 m/s\(^{-1}\) air velocities

One can notice that time constants decrease when increasing the flow velocity because of a larger surface over volume ratio exposed to the flow. Finally, even if the repeatability is good, such a calibration method remains however quite difficult to perform because the fragility of the sensor increases when the wires dimension decreases and the fluid flow increases.

**b) Radiative calibration**

This calibration method is based on a radiative excitation produced by a continuous argon laser [34, 35]. A set of two spherical lenses allows to locate the beam waist on the junction and an optical chopper generates a periodic modulation of the continuous laser beam. In order to avoid parasitic turbulences around the junction, the sensor is placed in a transparent enclosure (Figure 2.12.).

![Figure 2.12. Radiative characterization setup](image)

Lecture 5: Measurements with and without contact in heat transfer: page 14
The signal obtained is close to a first order response which gives immediately the sensors dynamic performances. Time constants decreases as diameter and heat transfer (the laser power) increase (Figure 2.13.). This is consistent with the effect of an increasing value of the power density or a decreasing of the beam radius that both acts on the power to heated mass ratio. Table 2.6 presents the radiative time constant for all the thermocouple junction diameters and the explored frequency bandwidth is ranged from 5 to 2274 Hz.

2.2.3. Microthermocouple designs

Different methods are used to design a thermocouple probe. It consists of a sensing element assembly, a protecting tube and terminations. Two dissimilar wires are joined at one end to form the measuring junction which can be a bare thermocouple element twisted and welded or butt welded. The protecting tube protects the sensing element assembly from the external atmosphere by a non ceramic insulation, a hard fired ceramic insulator or a sheeted compact ceramic insulator.

The thermocouple probe consists of two wires inserted in a ceramic double bore tube with length and external diameter depending on the experimentation. The wires are cut with a razor blade to produce a flat edge perpendicular to the axis. To realize the junction the thermocouple wires are connected to a bank of condensers (Figure 2.14.).
The two extremities are approached together in the same time and the beaded junctions are made by a sparking method. The energy release produced by the couple voltage-capacitance is sufficient to weld together the wires. One advantage of this technique is that the resulting junction diameter is not significantly greater than the wires one (Figure 2.15.). Except low mass and specific heat, another consequence is that the cross-sectional area of the wire itself can be used to calculate time constants. A drop of glue can deposited at the tube extremity and pushed down around both wires to minimize the probe fragility.

2.3. Temperature measurement in semi-transparent medium

The exterior glazing plays a leading role both in terms of heat losses and in terms of solar gain. The determination of surface temperatures of glass works in the heat balances and errors on these values can lead to significant differences on the prediction of energy consumption of a dwelling. Moreover, these temperatures, as all the surface temperatures of walls forming the building envelope, play a key role on the concept of thermal comfort. Indeed, cold surfaces in winter, hot in summer, the windows are at the root of many problems of radiative asymmetries.

These considerations illustrate the need for good knowledge of surface temperatures of semi-transparent materials when we are confronted with experimental apparatus comprising semi-transparent media. There are different methods for measuring surface temperatures. Two large families of experimental methods are commonly used: methods based on radiative measurements of radiation emitted by the surface and methods called “with contact”, using thermometric sensors set up on the surface of the medium when the measurement is direct or in the middle when it is done indirectly by extrapolating the temperature field to the surface. In the latter case, to know, accurately, the surface temperature of a material, thermometer elements are placed in the middle and at different depths in order to know the distribution of temperature field in the normal direction to the surface. Extrapolation of this field normally gives the surface temperature $T_s$. To make the extrapolation of internal temperatures, a formulation of the temperature field inside the medium is necessary to coincide satisfactorily with the measured sensor positions.

The advantage of an indirect measurement method is that it leads, when it can be used, to safer and more accurate results than with direct methods. The reason is that it does not cause virtually disturbance of the surface temperature. However, it is much difficult to implement, and even impossible in the case of glass materials. Indeed, it is necessary to include thermometer elements like thermocouples in the material during the molding. However, the melting of glass and metals used to manufacture thermocouples are relatively close, hence the great difficulty of implementation. The tests have been conducted to date have been unsatisfactory.

So it is with a semi-transparent type PMMA (plexiglass material that is formed by polymerization), obtained by cold molding panel that reference could be made. With the aim to validate various measurement methods for the determination of surface temperatures of semi-transparent media, several
laboratories have contributed to a "concerted research action" (A.R.C.) of the CNRS at the end of 80th. Even if it dates, the different results of this work [36] remain a reference in the topic.

An experimental apparatus has been set up to simulate various boundary conditions around a reference semi-transparent slab [37, 38] with dimensions 140x140 mm and 8.06 mm width.

The results summarised here (paragraph 2.3.2) present laboratory one (without wind) and in situ one, with real meteorological conditions.

To limit the disturbance introduced by the thermocouples inserted within the material, it is necessary that wires be as thin as possible (we have chosen for our part 8/100 mm thermocouple diameter) and low absorbency. In addition, the wires should be placed in an offset manner relative to the direction of the incident radiation to prevent shadows cast by opaque elements are not influencing the other thermocouples.

Furthermore, various studies have been conducted to estimate the disturbance brought by the thermocouples embedded in a semi-transparent. The results obtained by three different methods are given in paragraph 2.3.3.

2.3.1. Specifically problems in semi-transparent medium

When the material is opaque and homogeneous, there is the presence of pure conduction. In steady state, temperature extrapolation is relatively straightforward, especially in the case of unidirectional fields for which the law of temperature is linear, logarithmic or hyperbolic according it is a problem plane, cylindrical or spherical symmetry.

With a semi-transparent material, especially subject to radiative flux on the surfaces, heat transfer occurs by both conduction and radiation.

The radiative flux at a point of the semi-transparent material comes from the portion of radiant flux transmitted by the incident or reflected on the interfaces and the flux emitted by the material itself placed at a certain temperature level.

Part of the flow corresponding to the emission of the medium is usually negligible when one is near room temperature, which is the case in problems of thermal building. However, in the field of high temperatures, the material emission must be taken into account, as it becomes dominant.

We are thus led to put us on several levels of complexity in the search for laws of temperature distribution used in our methods for solving inverse problem. A purely conductive models taking into account the incident radiation as a volumetric internal heat source, in various cases of absorption of radiation by the middle is convenient for low temperature level. More complex, coupled models because they take into account at the same time the conduction and radiation are necessary for high temperature problems.

2.3.2. Contact surface temperature measurements

Obtaining the surface temperature of a semi-transparent by contacting a temperature sensor is a delicate manipulation and subjected to many errors [36, 39], largely due to the method used and specific properties of such a material. When this measurement is in situ, additional difficulties arise, related to heating and / or cooling of the sensor exposed or unexposed to sunlight and / or wind outside [40-43].

Interesting experimental and theoretical work on surface temperature measurement through contact has been carried out by Bardon and Cassagne [44] on opaque materials. Numerous authors developed such work, but on semitransparent materials. As far as artificial sites are concerned, we can cite work by Cerruti [38] and Werling [37], and, for real sites, work by Grenier [41] and Moreau [42] can be mentioned.

To measure the surface temperatures, the largest errors are due to the interaction temperature sensor / environment: the temperature field within and on the surface of the medium is locally perturbed by the presence of the sensor. The errors directly related to the thermoelectric phenomenon
used are generally of second order. The disturbance can be explained by the superposition of several effects already found to measure surface temperature on opaque medium:

- The effect of macroconstriction
- The effect of mask
- The effect of contact
- The effect of fin
- The effect due to the presence of an internal source of heat within the sensor

Glass and especially P.M.M.A. are relatively insulated materials. Also, the resistance of macroconstriction is often much greater than the contact resistance. The effect of macroconstriction plays an essential role in the measurement error. The presence of a contact disk can significantly reduce this effect.

The presence of contact resistance and the shift of the sensitive element of the sensor are often secondary roles. A good thermal contact is necessary, however, in the case of very small sensors (the number of contact points are then reduced) this is more sensitive to the glass, better thermal conductor than PMMA.

The effect of fin due to the presence of the physical link between the sensor and measuring equipment has to be minimized: for this the wires constituting this link have to present a radius, a thermal conductivity and a surface exchange coefficient as low as possible.

If the masking effect due to the shadow of the sensor in the MST in the presence of short wavelength radiation cannot be taken into account by the model of the semi-infinite bar, a simplified approach to the problem posed by the absorption of such radiation on the surface of the bar can be addressed through the concept of equivalent temperature.

![Figure 2.16. Thermocouple insertion inside semi-transparent material made of PMMA.](image)

We used a remarkable experimental system to evaluate measurement error. This comprised a semitransparent plastic material known as polymethyl methacrylate (PMMA) with a thickness of 8.0 mm and in which three 0.08 mm diameter thermocouples are inserted (Figure 2.16.). We therefore chose a similar material whose general properties are close to those for ordinary glass. The main difference concerns the conductivity coefficient, which is equal to 0.2 W m⁻¹ K⁻¹. This semi-
transparent reference material was manufactured by the Thermokinetic Laboratory of the University of Nantes.

We have exploited the internal measurement considering a Beer absorption law with a grey medium. Beer's law can take into account a simplified propagation of thermal radiation within the material. The radiation / matter interaction occurs during the clash between the photons of sunlight and the atoms constituting the material. Some of these photons can be absorbed, and thus yield their energy in the middle. Beer's law reflects an exponential decay of light entering an absorbent material. If $E$ is the total solar irradiance normally incident on the MST and $\rho$ the reflectivity of the first interface, the illumination $E(x)$, calculated at depth $x$ is given by the expression:

$$E(x) = (1 - \rho)Ee^{-kx}$$

So, the reference surface temperatures are calculated with the equations:

$$T(0) = \frac{(1-\rho)E}{\lambda k} + B$$
$$T(e) = \frac{(1 - \rho)E}{\lambda k} e^{-ke} + Ae + B$$

$A$ and $B$ being 2 constants determined using the internal temperatures and thermocouples positions, $\lambda$ the thermal conductivity and $\rho$ the reflectivity of the semi-transparent medium. $k$ is called the coefficient of linear absorption. It is an intrinsic characteristic of the medium studied.

First, we present some laboratory results [37, 39]. A device can reproduce conditions of sunshine, temperatures outside and inside a semi-transparent wall. Studied wall is placed between two environmental chambers made of exchanger plates, which temperature is regulated by means of thermostatic bath. The inner sides of the cube-shaped boxes are approximately 1m. The radiation is produced by lamps. A given sensor for various types of radiation protection is discussed in four test conditions (table 2.7.).

Three types of sensors were tested:
- Type K thermocouple, diameter 0.2 mm
- 100 Ω platinum probe “ultra 7”, size 2.54 x1, 27x0, 51mm natural color white
- thermistor “YSI.46043” shaped ball of diameter 2.5 mm natural colored black.

Figure 2.17. gives the measurement error in the four test conditions that were set. We can see that the best results are obtained with thermocouples protected by the incident radiation with a very reflective coating. Conversely, we realize that errors can reach values very important in the case of the thermistor that is relatively thick, or in the presence of radiation with absorbing coatings.

Lecture 5: Measurements with and without contact in heat transfer: page 19
Second, several experimentations have been made in real conditions.

Some results of a first study [40] are presented respectively for two cases of protection of thermocouples: cover plate and plain white paint. We get a negative error for a low illumination and with the presence of significant winds. Indeed, the thermocouple surface absorbs some of the incident solar flux, which causes heating faster than PMMA. The results remain the best in the case of a protective aluminum. Moreover, the measurement error is positive and greater than 1°C on the other side (x = e) is explained by the poor contact between the thermocouple surface and PMMA because of the protection under thermocouple, and also by inappropriate extrapolation of the temperature of the face x = e, in effect, the thermocouple located inside the PMMA and the closest to that face broke at the time of testing and extrapolation was made with two internal thermocouples.

The influence of wind on the measurement error is very significant: the error decreases significantly for speeds above 2.5 m/s. This is explained by the effect of fin, which tends to cool the surface thermocouple, which causes a reduction in measurement error in the presence of high light.

A second series of tests [43] were also conducted to compare simultaneous measurements by different possible cases of thermocouples attached to the outer surface of the PMMA (Table 2.8.).

These tests were repeated for several cases of coatings on the rear panel: aluminum foil, black paper and white paper. We note that if the solar irradiance is very strong, best results are obtained with the cover plate and black paper on the back plate. Moreover, in the presence of low solar irradiance which is actually a case of diffuse flux, the best results were obtained with ordinary white paint protection, aluminum protection giving results slightly worse.

We also find a systematic bias that tends to reduce the measurement error of about 0.08 °C when the connecting wires are not glued to the surface, the wires being submitted to convective effects causing the decrease of measurement error in the presence of illumination.

Direct measurements by contact, because of their low cost and ease of implementation are the most used. However, errors of measures appear significant if we do not take precautions. Also, it is good for a given sensor to apply corrections on the raw measurements into account the type of protection, levels of indoor and outdoor temperatures and mostly sunshine. Such a correction can be established experimentally, as we have done, or by using a numerical model.

2.3.3. Internal temperatures

Using these thermocouples we are able to define an internal temperature field allowing us to determine the real surface temperature of the semi-transparent material by extrapolation. However, as solar radiation passes through the semi-transparent material (PMMA), internal thermocouples will absorb such radiative flux and their thermal behaviour will become equivalent to that for an internal heat source. Therefore, to calculate the real surface temperature these measurements have to be corrected. Several models were developed. Using the Cerruti model [38, 36, 45], we can quantify radiative heat transfer inside a semitransparent material and, consequently, the error due to solar radiation absorption by internal thermocouples.

The inverse methods that were presented are based on the assumption that we know the temperature at two points in the studied medium, and they led us to the field of internal temperature and more particularly to surface temperatures.

However, the two internal temperatures that are measured using thermocouples are not exactly the temperature of the medium at the point considered, because of the disruption brought by the wires themselves.

It is therefore advisable to properly estimate these disturbances, with three possible methods: images, Green's functions and finite differences methods.

In these methods, the wires of the three thermocouples are considered gray body subjected to illumination. It is assumed that the entire flow absorbed by the wires is returned by conduction within the surrounding environment. In these circumstances, to represent the thermal perturbation caused by the thermocouples will take into account three sources of heat positioned to linear abscissa x1, x2 and x3.

For a unit length of yarn absorbed flux is given by the expression:

\[ \Phi_a = \alpha_I \cdot d_e \cdot E(x) \text{ in W/m} \]

where \( E(x) \) is the illumination at the point considered, \( d_e \) wire diameter and \( \alpha_I \) the dimensionless absorption coefficient of the wire.
2.3.4. **Conclusion.** Measuring a surface temperature of a semi-transparent material is a delicate operation. The comparative study is presented with use of a thermocouple contact shows a large disparity in results depending on the type of protection. The best results are obtained with a cache of aluminum or white paint.

In addition, corrective models have been produced and allow quantification of the measurement error depending on weather conditions.

2.4. **Error introduced by the disturbance of the local temperature using thermocouples**

2.4.1. **Introduction**

Whatever the selected measurement method, it is accompanied by parasitic effects which must be well-known. The resulting errors can be classified in two categories:

- the ones that are directly related to the thermometric phenomenon, they correspond to the inaccuracy on the measurement of thermometric quantities and to the parasitic effects attached to this phenomenon. It is not here the main topic, but they are not less important. We will quote simply for memory: singularities met in the laws of variation of electrical resistance due to structure modifications (allotropic transformations…), with chemical attacks… and for the thermoelectric circuits, the many parasitic effects such as f.e.m. induced, modifications of the thermoelectric force due to heterogeneities, modifications of structure, junctions nonspecific and not isotherms.

- the others, independently of the selected sensor are related to the fact that the interaction between thermometer, medium and environment causes a local disturbance of the temperature field therefore the local temperature is no more the one that exists before thermometric sensor settling.

In the following, we will present an error analysis and models to describe the local disturbance due to the presence of the sensors. These results come from various works realized at Laboratoire de Thermocinétique, Nantes (Bardon [46], Cassagne [47, 48])

2.4.2 **Error analysis and model**

2.4.2.1 **Surface temperature measurement**

The surface heat exchanges are modified by the presence of the sensor which does not have the same thermophysical and radiative properties and the same convective heat transfer as the medium to which it is applied. Therefore, a parasitic heat flow is transferred from the medium towards the sensor then from the sensor towards the environment as illustrated in figure 2.18. for surface temperature measurement.

![Figure 2.18. Surface temperature measurement](image-url)
A heat generation or absorption closed to the sensor or to its connection can also occur. All these transfers induce, at the measurement location, a local temperature disturbance which can be either positive or negative according to the heat direction (going in or out). The temperature is no more $T$ but $T_p$. Moreover, the sensor temperature is not usually equal to $T_p$ because the imperfect contact conditions between sensor and medium involves a temperature discrepancy $T_p-T_c$ which increases as the thermal contact resistance or the heat flux increases.

For an opaque medium, the following three effects are combined:

1. the effect of convergence of heat flux lines towards the sensor (macroconstriction effect),
2. the effect of thermal contact resistance which involves a temperature jump at the sensor/medium interface, and
3. the fin effect which corresponds to the heat transfer towards the outside (over the sensor and along its connection wires).

The measurement error is then:

$$\varepsilon(t) = T(t) - T_c(t)$$

2.4.2.2 Temperature measurement within a volume

For temperature measurement within a volume, the analysis is similar to the previous one. The error independently of the chosen sensor depends on the fact that the sensor temperature almost never coincides with that of the small element which it replaces. The thermophysical characteristics of the sensors ($\lambda$, $\rho$, $c$) and its radiative properties are different from those of the medium.

Heat transfer within the medium is modified by the presence of the sensor and similarly to surface temperature measurement, a local disturbance of the temperature field appears due to the heat transfer from the medium to the outside through the sensor. One still finds the three effects of: 1) convergence of the heat flux lines towards the sensor. 2) the thermal contact resistance effect 3) the fin effect. In addition the error is still: $\varepsilon(t) = T(t) - T_c(t)$

2.4.2.3 Error model

The study of the error related to the disturbance of the local temperature requires the solution of a multidimensional heat transfer problem with various possible configurations and boundary conditions. In this section, one will use relatively simple but very typical models that will clearly show the respective role of conduction within the medium, of non perfect contact between sensor and medium and finally the heat exchanges towards the environment. Most of the conclusions could be extended to numerous others configurations.

We will suppose that the heat exchanges of the medium or of the thermometric connection with the environment can be represented by the heat transfer coefficient, $h$, and the outside equivalent
temperature, \( T_E \). It is known, for example, that for a surface which absorbs a heat flow \( F \) (radiation coming from a high temperature heat source) which exchanges by convection with a fluid at \( T_f \) temperature and by radiation with walls at temperature \( T_0 \), one have:

\[
h = h_c + h_r
\]

\[
T_E = h_c T_f + h_r T_0 + F
\]

where \( h_c \) is the convection heat transfer coefficient, \( h_r = 4 A \sigma T_m^3 \) the radiation coefficient (\( A \) is a coefficient which depends on the emissivity and of the relative location of surfaces between which the radiative heat exchange occurs, \( T_m \) is an intermediate temperature between \( T_0 \) and that of the surface).

2.4.2.3.1 Steady state surface temperature measurement of an opaque medium

One will investigate surface temperature measurement on an opaque medium of thermal conductivity \( \lambda \) with a simplified sensor having the shape of a rod perpendicular to the surface (figure 2.20). Far from the sensor, the medium is at the constant temperature \( T \). The surface of the medium is assumed adiabatic except at the contact area \( S \) with the sensor.

\[ T - T_p = r_M \phi \]

\[ T_p - T_c = r_c \phi \]

The three following effects occur due to heat leakage through the sensor towards the outside:

b) The contact resistance effect: responsible for the \( T_p - T_c \) temperature drop, it is expressed by:

\[ T_p - T_c = r_c \phi \]
c) **The fin effect:** It is responsible for the heat transfer between the connection of the sensor and the environment. Whatever the assumed shape of the connection (rods with uniform or variable section) the heat flux $\phi$ transferred from the face at $x = 0$ to the environment is linked to the temperature difference (between $T_c$ at $x = 0$ and the equivalent outside temperature $T_E$) defined by:

$$T_c - T_E = R_E \frac{\phi}{2.3}$$

where $T_c$ is the temperature at $x = 0$, $T_E$ the equivalent outside temperature and $R_E$ the total thermal resistance between the face $x = 0$ and the environment. It depends in particular on the geometry, the heat transfer coefficient and the thermal conductivity $\lambda_E$ of this external connection:

$$R_E = \frac{1}{(\pi y_E \sqrt{2 h E \lambda_E y_E})}$$

for a thermocouple assumed as a rod of radius $y_E$. From relations (2.31, 2.32 and 2.33), one can deduce the heat flux: $\phi = \frac{T - T_E}{r_M + r_c + r_E}$ and the measurement error:

$$\delta T = k (T - T_E)$$

(2.34)

with $k = \frac{1}{1 + \frac{r_E}{r_c + r_M}}$ (2.35)

The error is thus proportional to the measured and equivalent outside temperatures difference ($T - T_E$), the “error coefficient” $k$ is all the more small as the sum of resistances of macro-constriction $r_M$ and contact $r_c$ will be small compared to the external resistance $r_E$. Therefore, it results that:

- For measurements on a high thermal conductivity medium (metal), $r_M << r_c$, the thermal contact conditions determines the errors
- For measurements on a low dielectric material, $r_M > r_c$, the effect of macroconstriction determines the error.
- The roles of $r_E$ and $T_E$ are finally very important. One needs the largest possible $r_E$ and $T_E$ nearest to $T$ (probe with heat flux compensation). It is worth to focus one’s attention to the heat flux $\phi_E$ generated on the surface of the connection wire. If $T_E$ can becomes much higher than $T$, the error is changed by sign and is of great amplitude: it is necessary to avoid the external radiation of source on the connection. These conclusions, found for the temperature measurement on an opaque medium and for a simplified configuration of a sensor having the shape of a rod perpendicular to surface, remain valid with slight differences for real configurations.

2.4.1.3.2 **Transient surface temperature measurement of an opaque medium**

For a fast sudden contact between an opaque medium and a sensor assumed as a rod and perpendicular to its surface, the error becomes function of time: $\varepsilon(t) = K(t) [T(t) - T_E]$. It remains proportional to the temperature difference: $T(t) - T_E$.

The coefficient $K(t)$ is maximum for $t \to 0$ and decreases for higher $t$ values. For $t \to \infty$, one have: $K(T) \to K(\infty)$ which is obtained for a steady state. The contact conditions between sensor and medium are of great importance:

- If $r_c \neq 0$, $K(0) = 1$, the error is about 100% at $t=0$ and decreases all the more the contact between sensor and medium is good.
- If $r_c = 0$ (perfect contact), the initial error is smaller.
\[ K(0) = \frac{b}{b + b_c} < 1 \]

where \( b = \sqrt{\lambda \rho c} \) and \( b_c = \sqrt{\lambda_c \rho_c} \) are the medium and connection effusivities.

One can characterize the thermal inertia by the time response \( x\% \), such as (figure 2.21):

\[ \frac{K(t_x) - K(\infty)}{K(0) - K(\infty)} = x \]

Figure 2.21.

For the same sensor \( t_x \) depends strongly on the characteristics of the medium and of the connection medium/sensor/environment. For a conducting medium, \( t_x \) depends strongly on \( r_c \) which appears as the main factor that determines the sensor inertia. \( t_x \) decreases when \( r_c \) decreases. It is the same thing if the diameter of the connections is reduced.

For fast transient evolutions, it is worth to weld wires on the surface, so that \( r_c \to 0 \), and to use wires as thin as possible. In this case \((r_c \sim 0)\), the thermal inertia \( t_x \) is primarily determined by the establishment time \( t^* \) of the macro-constriction phenomena within the medium. In practice, this phenomenon remains extremely localized within the immediate vicinity of the sensor (hemisphere of radius \( 10y \)), one can deduce an order of magnitude for \( t^* \) by considering the characteristic time \( t^* \approx 100y^2/a \) associated to this hemisphere. \%. One can consider that, at this time \( t^* \), constriction is established at \( 97\% \). One can thus consider that \( t_x \sim t^* \approx 100y^2/a \). For temperature with insulating mediums, \( r_c \) does not have any effect but \( t_x \) is much higher. For a transient evolution with a characteristic time \( t_c \) it is worth to choose a sensor for which \( t_x \ll t_c \). In this case, as soon as \( t > t_x \), the error will reach, at every moment, its minimal asymptotic value and the steady error model \((K)\) could be applied.

2.4.2.3.3 Temperature measurement within a volume

In this case, the connection wires usually do not follow an isothermal path on a sufficient length, therefore heat leakage through the sensors occurs. Measurements within a volume are in general much easier than on a surface and errors are usually smaller. However their analysis is more difficult to carry out especially because of the interaction between the connection wire and the medium. In addition, a cavity has to be realized for sensor introduction. Therefore, the cavity and sensors don’t match exactly, so there exists, between them, some residual space filled with air, grease, glue... which introduces a thermal resistance between sensor and medium. The measurement errors introduced by these phenomena are qualitatively rather similar to those described for surface temperature measurements. Lastly, for long enough isothermal path, heat transfer between sensor and environment is negligible, the differences between thermophysical characteristics (conductivity, heat capacity) of the medium, of the probe or the wire of connection or residual space, introduce a localized disturbance of the thermal field, and a measurement error remains, but this one is much weaker. An example is provided in figure 2.22.
With this configuration the previous error model (2.34. and 2.35.) is still valid, the value of \( r_c \) and \( r_M \) being different. If we consider that the sensitive element of the sensor with a length \( L \), and a radius \( y \), which recovers its surface \( S \), is isothermal and that its temperature is \( T_c \) (figure 2.22.). The contact between the probe and the medium is supposed to be imperfect, therefore for the whole surface of the sensor, the thermal contact resistance \( r_c \) is:

\[
 r_c = \frac{R_c}{S} = \frac{1}{2\pi \lambda \ell} \log \frac{2\ell}{y} \quad \text{if} \quad \ell \gg y
\]

### 2.4.3 Practical consequence and examples, semi intrinsic thermocouples

#### 2.4.3.1 Practical consequences

The steady state error model for the simple configuration allows some important features, most of them being valid for other configurations:

1) first of all even for perfect contact \( r_c = 0 \) there is an error which depends on the ratio \( r_M/r_E \).

2) if the medium is a high thermal conductivity material, the macro-constriction \( r_M \) will be usually small relatively to \( r_c \) and the error will be especially determined by \( r_c \). Thus, one must take care that \( r_c \) is small and remains stable. The contact pressure will have to be high and constant, surface will have to be plane without waviness, the interstitial medium with the highest possible thermal conductivity (welding, grease...). In addition, one should avoid oxide films as well as mechanical shocks and vibrations which can modify considerably \( r_c \) and consequently the measurement error.

3) For measurements on an insulator, \( r_M \) is large, usually much higher than \( r_c \). Thus, the macro-convergence effect is the main factor in the measurement error and one can reduce it by increasing the radius of the sensitive element without increasing the section of the connections (figure 2.23.). A contact disc of high thermal conductivity material will be used.

4) Whatever the type of measurement, the fin resistance \( r_E \) should be as high as possible. The transversal area, the conductivity, the heat transfer coefficient have to be chosen the smallest.
possible. One also should have low emissivity surface, connection protected from high
temperature fluids movements or radiation, $T_E$ being modified in those situations. One should
note that having an insulating layer on the metallic wire of the thermocouple can increase the
side heat transfer and therefore the measurement error.

5) Finally, the error is all the more small as $T_E$ is close to the temperature to measure $T$. It
changes with $T_E$. At the price of a technological complication, one can add an external heat
source on the connection so that its temperature $T_E$ is controlled in order to stay a close as
possible as $T$. In this case, one reduces considerably the heat transfer and consequently the
error of measurement. This principle is well known as “compensated heat flux sensors”.
However for correct measurement, the thermal resistance $r_E$ should stay high in order to
prevent the compensation heating from disturbing the temperature field in the medium.

2.4.3.2. Application -for steady state temperature measurement for a thermocouple with and without a
contact disc
The two thermocouple wires are considered as a unique rod with a radius $y_B = 0.5$ mm, an infinite
length, an average thermal conductivity $\lambda_B = 15$ W.m$^{-1}$.K$^{-1}$ and a heat transfer coefficient $h_B = 5$ W.m$^{-2}$K$^{-1}$.
The fin thermal resistance is:

$$r_B = \frac{l}{\pi y_B \sqrt{2h_B y_B \lambda_B}}$$

(rod approximation)

Thus, the connection resistance is:

- $r_E = r_B$ without contact disc,
- $r_E \approx r_B + \frac{l}{4y_B^4 \lambda_D}$ with contact disc

($\frac{l}{4y_B^4 \lambda_D}$ is the resistance due to heat flux convergence from $y$ to $y_B$ inside the sensor).

Table 2.9. provides the values of $r_M$, $r_c$, $r_E$ and $K$ and for various $\lambda_D$ with and without disc ($y=y_B=10$ mm, $\lambda_D = \lambda_B$) and for different values of $R_c$ per unit of area:

2.4.3.3. Temperature measurement with semi intrinsic thermocouple

In this device, one uses the medium M itself (presumably electrically conducting) as one item of the thermocouple (figure 2.24.). Compared to a traditional sensor, this device has several advantages:
- it has only one connection wire instead of two, thus heat leakage is reduced and the thermal resistance \( r_E \) is twice larger.
- the measured temperature \( T_\mu \) is intermediate between \( T_p \) and \( T_c \) (figure 2.24.)

![Figure 2.24. Semi intrinsic thermocouple](image)

For times \( t > t_c \) (time constant), \( T_\mu \) is such that:

\[
\frac{T_p - T_\mu}{T_\mu - T_c} = \frac{\lambda_A}{\lambda_M}
\]

The error \( \varepsilon_i = T - T_\mu \) is thus lower and the contact resistance effect is partly cancelled. For steady state, the error is such that:

\[
\varepsilon_i = K_i (T - T_E)
\]

\[
K_i = \frac{r_M + r_c}{r_M + r_c + r_E}
\]

This error is considerably lower than with a traditional thermocouple (2 to 5 times) and this as much more as the wire thermal conductivity \( \lambda_A \) is small compared to \( \lambda_M \). In transient mode, error and thermal inertia are greatly reduced (Bardon [46], Cassagne [47]). However, the calibration of the semi intrinsic thermocouple is almost always required. It is usually performed by comparison with a traditional thermocouple.

2.5. Heat flux measurement: direct and in direct methods

2.5.1. Direct measurement

2.5.1.1. Heat flux sensor with gradient (Ravaltera [49])

The principle of this heat flux measurement consists in directly applying the Fourier’s law by measuring a temperature difference within the wall itself (intrinsic method) or by covering it with an additional wall (heat flux sensor-HFS-). The surface characteristics of this HFS should be close to those of the wall. The wall of the HFS can be homogeneous (the temperature difference is measured between its two main faces -normal gradient heat flux sensor- figure 2.25.-) or it can be heterogeneous creating heterogeneous temperature that is measured (tangential gradient heat flux sensor – figure 2.26.-).
The installation of such HFS on a wall, more or less disturbs the heat flux which crosses it. All must be done so that internal and contact thermal resistances are minimal. In these devices, the measurement of the temperature difference is performed using several thin film thermocouples or thermoresistances. These HFS can work whatever the heat flux direction in steady state or for slowly variable temperature.

2.5.1.2. Inertia heat flux sensor and heat flux sensor with electric dissipation (zero method)

Inertia heat flux sensors works only for variable temperature and if the heat flux is received by the wall. The HFS replaces a piece of the wall and is isolated from this one. Its surface characteristics are identical to those of the wall. The temperature increase of the HFS is proportional to the absorb heat flux and inversely proportional to its capacity (figure 2.27.). The choice of this one is very important because it determines the measurement sensitivity.

The principle of this HFS with electric dissipation consists in substituting a piece of the wall at its surface with a small heating part insulated towards the wall (fig. 2.28.). The electric heating output is adjusted so that the surface temperature of the wall and of the heating part are equal ($\Delta T = 0$). Thus, the dissipated electric flux is equal to the heat flux which leaves the wall in its immediate vicinity. This HFS works only for heat flux leaving the wall and for steady state or slowly variable temperature.

2.5.1.3. Enthalpic heat flux sensor

They are used to measure the heat flux coming from the outside. The HFS replaces an element of surface of the wall and is insulated from this one (figure 2.29.). An initially temperature controlled fluid circulation is heated by the heat flux which induces an enthalpic flow rate. For a correct measurement, the fluid temperature must be adjusted so that wall and HFS temperatures are almost equal. This condition is not always realized and can be an important source of error. The choice of the heat-storage capacity of the fluid also is important.
2.5.2. Indirect measurement

One can obtained the surface characteristics (temperature $T$, heat flux $\phi$) from measurements realized within the medium and using inverse methods (figure 2.30.). This procedure involves solution of ill-posed problems. Indeed, one cannot insure a solution, its uniqueness or stability. To solve such difficulties, the technique consists in replacing the ill posed problem by a well posed approximate problem. The solution is found by minimizing a norm of least square type. A heat transfer model (analytical or numerical) is required to solve the direct problem at each optimization step. These methods require significant developments (Beck [50], Alifanov [51], Ozisik [52], Jarny [53]). They will not be presented here. We will just underline that the solution of the inverse problem allows to compute the temperature residuals between final and measured temperatures. These residuals are of great importance because they allow to check the validity of the chosen heat transfer model. If no signature is observed (the residuals are purely random) the model is correct, otherwise the model should be improved.

With regard to the theoretical aspects of the instrumentation, Bourouga [54] has proposed criteria for correct locations of thermocouples to obtained unbiased results and also optimized the experiment for wall heat flux or temperature estimation.

3. Thermometry without contact: radiative methods

4. Conclusion

Accurate temperature measurement is not an easy task. Errors depend on thermosensitive phenomena and also according to the sensors which can create local temperature disturbance and therefore bias. Very often, this latter error is ignored. In this lecture and for contact and non-contact temperature measurement, one have tried to provide to the readers the know-how in various situations (temperature measurement in fluids, in transparent medium, in opaque medium) in order to perform the best temperature measurements as possible.
